Effect of Oral Methylprednisolone on Clinical Outcomes in Patients With IgA Nephropathy
The TESTING Randomized Clinical Trial

 IMPORTANCE Guidelines recommend corticosteroids in patients with IgA nephropathy and persistent proteinuria, but the effects remain uncertain.

 OBJECTIVE To evaluate the efficacy and safety of corticosteroids in patients with IgA nephropathy at risk of progression.

 DESIGN, SETTING, AND PARTICIPANTS The Therapeutic Evaluation of Steroids in IgA Nephropathy Global (TESTING) study was a multicenter, double-blind, randomized clinical trial designed to recruit 750 participants with IgA nephropathy (proteinuria greater than 1 g/d and estimated glomerular filtration rate [eGFR] of 20 to 120 mL/min/1.73 m² after at least 3 months of blood pressure control with renin-angiotensin system blockade] and to provide follow-up until 335 primary outcomes occurred.

 INTERVENTIONS Patients were randomized 1:1 to oral methylprednisolone (0.6-0.8 mg/kg/d; maximum, 48 mg/d; n = 136) or matching placebo (n = 126) for 2 months, with subsequent weaning over 4 to 6 months.

 MAIN OUTCOMES AND MEASURES The primary composite outcome was end-stage kidney disease, death due to kidney failure, or a 40% decrease in eGFR. Predefined safety outcomes were serious infection, new diabetes, gastrointestinal hemorrhage, fracture/osteonecrosis, and cardiovascular events. The mean required follow-up was estimated to be 5 years.

 RESULTS After randomization of 262 participants (mean age, 38.6 [SD, 11.1] years; 96 [37%] women; eGFR, 59.4 mL/min/1.73 m²; urine protein excretion, 2.40 g/d) and 2.1 years' median follow-up, recruitment was discontinued because of excess serious adverse events. Serious events occurred in 20 participants (14.7%) in the methylprednisolone group vs 4 (3.2%) in the placebo group (P = .001; risk difference, 11.5% [95% CI, 4.8%-18.2%]), mostly due to excess serious infections (11 [8.1%] vs 0; risk difference, 8.1% [95% CI, 3.5%-13.9%]; P < .001), including 2 deaths. The primary renal outcome occurred in 8 participants (5.9%) in the methylprednisolone group vs 20 (15.9%) in the placebo group (hazard ratio, 0.37 [95% CI, 0.17-0.85]; risk difference, 10.0% [95% CI, 2.5%-17.9%]; P = .02).

 CONCLUSIONS AND RELEVANCE Among patients with IgA nephropathy and proteinuria of 1 g/d or greater, oral methylprednisolone was associated with an increased risk of serious adverse events, primarily infections. Although the results were consistent with potential renal benefit, definitive conclusions about treatment benefit cannot be made, owing to early termination of the trial.

 TRIAL REGISTRATION clinicaltrials.gov Identifier: NCT01560052

Immunoglobulin A nephropathy is the most prevalent primary glomerular disease, particularly in the Asia-Pacific region. Up to 30% of all people with IgA nephropathy will eventually develop end-stage kidney disease (ESKD); decreased kidney function, persistent proteinuria, and hypertension are the strongest risk factors. The use of renin-angiotensin system (RAS) blockade has been shown to reduce the risk of kidney failure in patients with high-risk IgA nephropathy and is thus guideline-recommended therapy. Despite this, a large proportion of individuals will still develop ESKD, so better treatments are required.

Although IgA nephropathy is an immune-complex-mediated glomerulonephritis, the role of immunosuppression remains controversial. A meta-analysis of previous trials suggested substantial benefit with corticosteroid therapy, but trial quality was suboptimal, most trials were single-center, and adverse outcomes were poorly reported. Additionally, the efficacy of corticosteroids in patients with impaired kidney function was not evaluated, and limited data exist for people of Eastern or South-Asian origin. Global guidelines currently suggest a 6-month course of corticosteroids for individuals with urinary protein excretion persistently above 1 g/d and an estimated glomerular filtration rate (eGFR) greater than 50 mL/min/1.73 m² after at least 3 months of appropriate supportive care. However, it is acknowledged that this weak recommendation is based on low-quality evidence.

In addition, a recent trial of immunosuppression in IgA nephropathy found that the addition of immunosuppressive to intensive supportive care in 162 European participants reduced proteinuria but did not reduce the rate of eGFR decline over 3 years. As a result, it remains uncertain whether corticosteroid therapy is beneficial in IgA nephropathy and how any benefits might trade off against potential risks.

The present study was designed to test the efficacy and safety of full-dose corticosteroid therapy in preventing clinically important kidney outcomes in patients with high-risk IgA nephropathy.

Methods

Study Design and Patients
The Therapeutic Evaluation of Steroids in IgA Nephropathy Global (TESTING) study was an investigator-initiated, multicenter, double-blind, randomized clinical trial comparing oral methylprednisolone with placebo on the risk of important kidney outcomes in people with IgA nephropathy receiving appropriate supportive therapy, including blood pressure control and RAS blockade.

The study was overseen by a management committee, coordinated by an academic research organization (The George Institute for Global Health), and designed to be conducted in up to 100 centers from China, Australia, India, Canada, and Malaysia. Ethical approval to conduct the trial was obtained from Peking University, the University of Sydney, and the ethics committees of each study center; all participants provided written informed consent. The study protocol is available in Supplement 1.

Key Points

**Question** Do corticosteroids safely prevent loss of kidney function in patients with IgA nephropathy receiving optimal supportive therapy?

**Findings** This randomized clinical trial that included 262 participants was stopped early (after 28 of the 335 planned events) due to a significantly increased risk of serious adverse events with oral methylprednisolone vs placebo (14.7% vs 3.2%, primarily excess infections); at that point, the primary efficacy outcome favored methylprednisolone (5.9% vs 15.9%).

**Meaning** Oral corticosteroid therapy was associated with an increased risk of serious adverse events; the effect on kidney outcomes remains uncertain due to the limited number of events.

Eligibility required a diagnosis of primary IgA nephropathy proven on kidney biopsy, an eGFR between 20 and 120 mL/min/1.73 m² (calculated using the Chronic Kidney Disease Epidemiology Collaboration creatinine equation), and urinary protein excretion greater than 1 g/d. Exclusion criteria included a strong indication, or contraindication, for corticosteroid therapy, based on the judgement of the treating physician (patients were included if the patient and physician had clinical equipoise regarding the use of the treatment), or the use of systemic immunosuppressive therapy in the previous year.

The full inclusion and exclusion criteria are detailed in eTable 1 in Supplement 2. Given the planned multinational recruitment and potential for differences in response by ethnicity, self-reported racial origin by patients was collected and recorded by the investigators, based on prespecified categories.

Randomization and Masking
Patients who were adherent to treatment and who had persistent proteinuria greater than 1 g/d during the run-in period were randomly assigned 1:1 via a password-protected encrypted website interface to receive oral methylprednisolone or matching placebo, stratified by region; proteinuria (<3 g/d or ≤3 g/d); eGFR (<50 mL/min/1.73 m² or ≤50 mL/min/1.73 m²); and kidney biopsy findings (endocapillary proliferation status [E1 or E0] according to the Oxford classification). Randomization was performed using a minimization algorithm based on the stratification variables; the algorithm was centrally generated and used by all centers to minimize any imbalances in key variables. Patients, investigators, site staff, and sponsors were masked to treatment assignment for the duration of the study.

Procedures
Potentially eligible participants entered a run-in period from 4 to 12 weeks, during which treatment was adjusted to ensure that they were receiving the maximum labeled or tolerated dose of RAS blockade, along with optimized blood pressure control according to Kidney Disease: Improving Global Outcomes (KDIGO) guidelines for glomerulonephritis and hypertension, for at least 3 months prior to randomization.

Downloaded From: http://jamanetwork.com/ by a Loyola University Health Sciences Library User on 08/14/2017
treatment consisted of 0.6 to 0.8 mg/kg/d of oral methylprednisolone or matching placebo (rounded to the nearest 4 mg and with a maximal dose of 48 mg/d) for 2 months, then tapered by 8 mg/d each month, with a total treatment period of 6 to 8 months.

Participants were followed up at regular intervals, for a planned mean of at least 5 years. Study visits occurred monthly for 3 months after randomization, then every 3 months until month 12, and every 12 months until the end of the study. Additional telephone or face-to-face (at the choice of the investigator) visits were required at 3-month intervals to ascertain kidney end points or adverse events.

Laboratory evaluation of all specimens was performed in a national central laboratory in China and at local laboratories in other countries. Serum creatinine levels were measured using enzymatic or Jaffe methods with calibration traceable to isotope dilution mass spectrometry.

End Points
The primary composite end point was initially defined as the first occurrence of a 50% decrease in eGFR, the development of ESKD (defined as a need for maintenance dialysis or kidney transplantation and adjudicated by a blinded, independent committee), or death due to kidney disease. Based on consensus recommendations from a workshop sponsored by the National Kidney Foundation and the US Food and Drug Administration on renal end points, the steering committee decided to modify the creatinine-based component of the primary end point to a 40% decrease in eGFR in November 2014, prior to knowledge of any results, while other components of the primary end point remained unchanged.

Secondary end points included the composite of ESKD, 40% decrease in eGFR, and all-cause death; the composite of ESKD, 50% decrease in eGFR, and all-cause death; and each of ESKD, death due to kidney disease, and all-cause death. The secondary end points also included proteinuria reduction evaluated by time-averaged proteinuria and eGFR slope across all postrandomization study visits. Prespecified exploratory end points included (1) a 25% decrease in eGFR assessed separately or as part of a composite with ESKD and all-cause death; (2) annual slope in the inverse of serum creatinine level; (3) proteinuria remission at months 6, 12, and 24; and (4) disappearance of hematuria at last follow-up. A statistical analysis plan (Supplement 3) was developed by a subgroup of the steering committee, blinded to any information about study outcomes.

Adverse Events and Safety
Predefined safety outcomes were all-cause mortality, total serious adverse events, serious infections, new diabetes, gastrointestinal hemorrhage, fracture or osteonecrosis, and cardiovascular events. Serious adverse events (SAEs) were defined according to the International Conference on Harmonization Guideline for Clinical Safety Data Management.

Interim Analyses and Data Monitoring
An independent data and safety monitoring committee (DSMC) met twice yearly to review efficacy and safety data; 2 formal interim efficacy analyses were planned when one-third and two-thirds of the primary end points had occurred, using stopping boundaries defined using the O’Brien Fleming method, while the decisions about stopping for harm were not based on predefined statistical rules. The DSMC could recommend terminating the study early if there was clear and substantial evidence of benefit or if the risk of adverse events was determined to likely substantially outweigh the potential benefits (Supplement 4).

Statistical Analysis
The initial sample-size calculations assumed an annual combined event rate for the primary end point (50% eGFR decrease, ESKD, and death due to kidney disease) of 7%, requiring 1300 participants to detect a 30% relative risk reduction in the primary end point with 90% power (α = .05). A 30% risk reduction was selected because it was the upper bound of the 95% confidence interval in a meta-analysis of previous trials assessing steroids for IgA nephropathy. After the primary end point was modified to include a 40% reduction in eGFR, the estimated annual event rate increased to 12% based on data from a large Chinese cohort and a previous trial, and the required sample size was reduced to 750 participants to provide more than 90% power to detect a 30% risk reduction with methylprednisolone. The trial was event-driven throughout, with a total of 335 primary outcomes expected over a mean follow-up of 5 years.

All analyses were conducted according to the intention-to-treat principle. The effect of treatment on the primary composite end point was estimated using an unadjusted Cox proportional hazards model. The proportionality assumption was assessed by plotting log{−log[S(t)]} and assessing whether the curves were parallel and with a test of interaction between time and treatment in the Cox model. Data for patients were censored at the date of death or the date of data extraction for those still alive. Because of small numbers, other composite end points as well as the individual components were summarized as the proportions of patients with at least 1 event and compared using Fisher exact test. Confidence intervals for risk differences were calculated using the Newcombe score method.

The yearly rate of eGFR decline was calculated as the mean of the individual slopes obtained from individual linear regressions of eGFR over time. Time-averaged proteinuria was calculated as the weighted mean of all postrandomization measurements, with weights representing the time elapsed since the previous measurement. Mean eGFR slopes and mean time-averaged proteinuria values were compared across treatments using t tests. Overall differences in eGFR and proteinuria over time were estimated using linear mixed models including all postrandomization measurements. Fixed effects included baseline measurement, month (as a categorical variable with 5 categories), treatment group, and the interaction between month and treatment group. A random intercept by participant was used to model within-participant correlations. Complete remission of proteinuria was defined as achievement of urinary protein level less than 200 mg/d, and partial remission as 50% or greater proteinuria reductions, with achieved urine protein
less than 1 g/d. Details on the analysis of exploratory end points are included in the statistical analysis plan (Supplement 3).

All P values were 2-sided, and P values less than .05 were considered to indicate statistical significance. Formal adjustment for multiple comparisons was not performed, but analyses were interpreted conservatively in light of the number of outcomes assessed, and effects on secondary outcomes should be considered exploratory.

The homogeneity of the treatment effects on the primary outcome across specified subgroups was tested by adding interaction terms to the Cox models, with predefined subgroups including proteinuria (<3.0 vs ≥3.0 g/d), eGFR (<50 vs ≥50 mL/min/1.73 m²), endocapillary hypercellularity on histological scoring (yes or no), and baseline maximum tolerated dose of RAS blockade (>80%, 50%-80%, and <50% achieved of maximum labeled dose). All analyses were performed using SAS version 9.4 (SAS Institute).

Results

Between May 2012 and November 2015, 523 potentially eligible patients were screened, of whom 262 (48.8%) were eligible and underwent randomization (136 to methylprednisolone, 126 to placebo) (Figure 1). Recruitment was stopped early, and study treatment discontinued among randomized participants, owing to an excess of SAEs (mostly infections) in the corticosteroid group, based on advice from the DSMC at a regularly scheduled meeting in November 2015 that concluded that the trial should not continue in its current form; the full recommendations of the DSMC are reported in Supplement 5. The steering committee accepted this advice and decided to terminate the study intervention on this basis on November 13, 2015.

At the time of this transitional analysis, participants had been in the study for a median of 25 months (range, 5.7-45.3 months). A total of 226 (86%) had completed study treatment and were in the follow-up phase at the time the steering committee made the decision to discontinue recruitment and study therapy.

Twenty-eight SAEs were reported in 20 participants (14.7%) in the methylprednisolone group compared with 4 SAEs in 4 (3.2%) in the placebo group (relative risk, 4.63 [95% CI, 1.63 to 13.2]; P = .001 by Fisher exact test) (Table 2 and Figure 2), equating to a risk difference of 11.5% (95% CI, 4.8% to 18.2%). Most adverse events occurred in the first 3 months of treatment. This was mainly driven by an excess of serious infections (2 fatal) among 11 participants (8.1%) in the methylprednisolone group, compared with no serious infections in the placebo group (risk difference, 8.1% [95% CI, 3.5% to 13.9%]; P < .001). One patient in the placebo group died of stroke after commencing dialysis. Effects on SAE rates were broadly consistent according to predefined baseline subgroups (eFigure 2A in Supplement 2), but small event numbers limited subgroup power.

The primary composite renal outcome occurred in 8 participants (5.9%) in the methylprednisolone group and 20 (15.9%) in the placebo group (hazard ratio, 0.37 [95% CI, 0.17 to 0.85]; P = .02; risk difference, 10.0% [95% CI, 2.5% to 17.9%]) (Figure 3), including 4 (2.9%) and 10 (7.9%) participants,
respectively, reaching ESKD (P = .10). A prespecified sub-
group analysis did not show evidence of significant differ-
ences in the effects of methylprednisolone on the composite 
kidney failure outcome in subgroups defined by baseline pro-
teinuria (<3.0 vs ≥3.0 g/d), kidney function (eGFR <50 vs 
≥50 mL/min/1.73 m²), histological lesions scoring (E1 vs E0 by 
Oxford classification), and dose of angiotensin-converting 
enzyme inhibitors or angiotensin II receptor blockers (eFigure 2B 
in Supplement 2) but was limited by the small number of 
primary outcomes.

The effects on secondary outcomes are listed in Table 3. 
Only 14 participants reached ESKD, with no clear difference 
between the randomized groups. Of these participants, 7 had 
a baseline eGFR less than 30 mL/min/1.73 m², and another 4 
had baseline eGFR between 30 and 50 mL/min/1.73 m². The 
effects on other components of the primary outcome were 
directionally similar but not statistically significant. Participants 
randomized to corticosteroid therapy had a lower risk of 
composite outcomes, including ESKD, all-cause death, and 
either 25% (risk difference, 22.6% [95% CI, 12.1% to 32.6%];

P < .001) or 40% (risk difference, 8.5% [95% CI, 0.7% to 16.6%]; P = .03) reductions in eGFR, but not composite outcomes including a 50% reduction in eGFR (P = .29). The mean annual rate of eGFR decline in the methylprednisolone group was –1.79 mL/min/1.73 m², compared with –6.95 mL/min/1.73 m² in the placebo group (difference, 5.15
Mean proteinuria during follow-up was significantly reduced in the methylprednisolone-treated group (1.37 [SD, 1.08] vs 2.36 [SD, 1.67] g/d; difference, −0.99 g/d [95% CI, −1.34 to −0.64 g/d]; P = .001) (Figure 4B). This was consistent with the overall difference estimated with linear mixed models (difference, −1.0 g/d [95% CI, −1.36 to −0.65]; P < .001). The proportion of individuals achieving either complete or partial remission of proteinuria at 6 months was 45.1% in the corticosteroid group vs 13.7% in the placebo group (risk difference, 31.4% [95% CI, 18.9% to 42.5%]; P < .001), with similar results at 12 months (52.2% vs 13.6%; risk difference, 38.5% [95% CI, 25.2% to 50.0%]; P < .001) and 24 months (48.2% vs 21.8%; risk difference, 26.4% [95% CI, 8.7% to 42.0%; P = .005). At 6 months, the rates of complete remission of proteinuria were 7.8% for the corticosteroid group vs 1.1% for the placebo group (risk difference, 6.8% [95% CI, 0.8% to 13.6%; P = .04) and of partial remission were 45.1% vs 13.7% (risk difference, 31.4% [95% CI, 18.9% to 42.5%]; P < .001). Microscopic hematuria (defined as at least 5 red blood cells per high-power field) was noted in 138 patients (62.2%) at baseline. Among those, 127 had at least 1 subsequent measurement, with 61 (48.0%) showing remission by the last visit. This occurred in 58.8% of participants in the methylprednisolone group vs 35.6% in the placebo group (risk difference, 23.2% [95% CI, 5.8% to 38.7%]; P = .01).

Discussion

This study assessed a full-dose corticosteroid regimen in patients with IgA nephropathy at high risk and found high rates of serious adverse outcomes due mainly to an increased risk of serious infections, resulting in the early cessation of recruitment to the trial. While proteinuria and eGFR levels were improved, and suggestions of potential benefit for the primary outcome were observed, there were too few primary outcomes to draw definitive conclusions about treatment efficacy from this trial.

The nearly 5 times higher risk of SAEs is a particularly important finding, given that many previous corticosteroid trials in IgA nephropathy have collected and reported adverse effects inconsistently. It is possible that the high rate of infections was related to the trial population or the specific treatment regimen used in this study; however, the Supportive Therapy for the Treatment of Progressive IgA Nephropathy (STOP-IgAN) trial also collected and reported detailed adverse-event data and found similarly high rates of severe infections among the immunosuppression group (8.1% vs 9.8%), including 1 death in the combination immunosuppression group. The excess of SAEs (mostly infections) observed in this study has implications for clinical decision making and treatment guidelines for the use of corticosteroids in IgA nephropathy. Future studies could also consider the use of prophylactic antibiotic therapy, which has not been used in any of the completed studies and is not recommended in clinical practice guidelines.

While interpretation of the primary results is limited, the findings are consistent with a meta-analysis of 9 smaller trials, which found that corticosteroid therapy was associated with a lower risk of composite renal outcomes (50% reduction in eGFR or ESKD; relative risk, 0.32 [95% CI, 0.15 to 0.67]).

Abbreviations: eGFR, estimated glomerular filtration rate; ESKD, end-stage kidney disease.
* P value for primary outcome calculated using survival analysis. Other P values calculated using t tests or Fisher exact tests.
† No deaths due to kidney failure were observed in the trial.
‡ Defined for each individual patient using the slope from least-squares linear regression of all eGFR estimates over time.
§ Defined as above, but excluding the treatment period with highest corticosteroid exposure from month 1 and month 3.
¶ Defined as above, but excluding the treatment period with highest corticosteroid exposure from months 1, 3, and 6.
© Defined for each individual patient using the slope from least-squares linear regression of all reciprocal of serum creatinine values over time.
© Defined as above but excluding the treatment period with highest corticosteroid exposure from month 1 and month 3.
© Defined as above but excluding the treatment period with highest corticosteroid exposure from months 1, 3, and 6.
© Total proteinuria remission is defined as complete or partial remission. Complete proteinuria remission is defined as 24-hour urinary protein less than 200 mg/d and partial proteinuria remission as proteinuria less than 50% of baseline by 24-hour urinary protein and less than 1 g/d.
© Defined as urinalysis revealing less than 5 red blood cells per high-power field at the end of the study or last available visit for those participants with microhematuria or macrohematuria at randomization visit.

These findings contrast with those from the STOP-IgA study, which randomized 162 participants to immunosuppression or supportive therapy alone for 3 years and found no effect on slope of eGFR decline or ESKD.13 Possible reasons for the difference in results include the fact that participants in the present trial were at higher risk because of higher mean baseline proteinuria levels and perhaps also because individuals of Eastern Asian origin (eg, China, Japan, Philippines, and Vietnam) may have more rapid rates of eGFR decline and kidney failure.20 The rate of eGFR loss among patients in the supportive-therapy group of this study was higher than that in STOP-IgA (~6.95 vs ~1.6 mL/min/1.73 m² per year), making detection of any benefit more likely. The annual rate of eGFR decline in STOP-IgAN was also lower than that observed in a cohort study21 and a recent trial,22 both from Europe. The longer period of RAS blockade in STOP-IgAN is another difference; however, the rate of eGFR loss in the placebo group did not slow appreciably with longer RAS exposure time during follow-up in the TESTING placebo group, and the effects did not differ by dose of RAS blockade. Although ethnic differences in response to treatment are possible, this is not suggested by the results of previous trials.9 The shorter follow-up of the present trial compared with the STOP-IgAN trial
isanotherpossiblereason. Ongoing follow-up of both studies is important to better define the longer-term kidney effects, particularly as the adverse events mostly occurred early, whereas the benefits appeared to accrue throughout follow-up.

The early increase in eGFR observed in the corticosteroid-treated participants raises the possibility that some of the eGFR effects may be due to sarcopenic effects of corticosteroid leading to reduced creatinine generation (eFigure 3 in Supplement 2) or due to corticosteroid-induced hyperfiltration.23,24 Excluding the creatininemeasuresduringthetreatmentperiodattenuatedthe difference in the rate of eGFR loss over time, but it remained significantly lower in the corticosteroid-treated group. The early reduction in proteinuria, as well as the difference in rates of the more clinically important primary outcome, suggest that potentially clinically important benefits are possible, which will be further clarified by the ongoing follow-up of study participants.

Strengths of this trial include the relatively large sample size. The ongoing participant follow-up will help to more accurately assess the efficacy of corticosteroids. This study also has several limitations. Although to our knowledge this is the largest trial reported to date among patients with IgA nephropathy, recruitment was stopped earlier than planned because of excess adverse events, so power was less than predicted, and both risks and benefits might be overestimated as a result. Most participants were of a single ethnicity, meaning ethnicity-based treatment responses cannot be assessed. The reliance on eGFR based on serum creatinine measurement is another limitation, particularly because corticosteroids may reduce creatinine generation.

Conclusions

Among patients with IgA nephropathy and proteinuria greater than 1 g/d, oral methylprednisolone was associated with an increased risk of serious adverse events, primarily infections. Although the results are consistent with potential benefit, definitive conclusions about treatment benefit cannot be made, owing to early termination of the trial.
